Abstract

This paper presents a new methodology to evaluate the impact of forecast errors on policy. We apply this methodology to the Federal Reserve forecasts of U.S. real output growth and the inflation rate using the Taylor (1993) monetary policy rule. Our results suggest it is possible to calculate policy forecast errors using joint predictions for a number of variables. These policy forecast errors have a direct interpretation for the impact of forecasts on policy. In the case of the Federal Reserve, we find that, on average, Fed policy based on the Taylor rule was approximately a full percentage point away from the intended target because of errors in forecasting growth and inflation.

Alexander Kapinos provided essential research assistance.

Introduction

Individuals, businesses, and government policymakers use economic forecasts as guides to many important economic and financial decisions. Thus, it is imperative to evaluate the accuracy of economic forecasts and determine the effects that they have on policy. There have been innumerable evaluations of these forecasts. While most evaluations focused on the accuracy of a particular variable, there have also been discussions about the appropriate procedures for evaluating multivariate forecasts (See Hymans, 1968; Clements and Hendry and subsequent comments, 1993; Eisenbeis, et al., 2002; and Komunjer and Owyang, 2007). The recent research has examined forecasts of multiple variables taking into consideration the characteristics of these multivariate forecasts such as the relative variances and co-movement of the series. However, these evaluations involving multiple variables were not done in the context of policy loss functions or decision rules.

In this paper we develop a methodology that can be used to jointly evaluate the forecasts of any number of variables that are made at the same time and quantify their policy implications. Because the methodology considers the policy forecast error of a decision, it is in the spirit of evaluating forecasts by considering the economic costs of prediction errors (see Clements, 2004; Granger and Pesaran, 2000a and 2000b; and Pesaran and Skouras, 2002). The methodology has general applicability and can be used to evaluate the effect that forecast errors have on many decisions. We ask the following question: How different would a policy decision have been if the policymakers had had perfect foresight instead of deciding on the basis of their forecasts?

To illustrate the applicability of this methodology, we use the Greenbook forecasts that are made by the staff of the Board of Governors of the Federal Reserve to determine their impact on monetary policy. The Greenbook forecasts are produced before each meeting of the Federal

Open Market Committee and contain projections on the economy up to eight quarters into the future. Many studies have already examined these predictions of the real output growth and inflation rate (e.g. Clements et al., 2007; Joutz and Stekler, 2000; Romer and Romer, 2000; Sims, 2002; Stekler, 1994). The previous studies have measured the accuracy of these variables individually. However, as these two variables are related and forecasted at the same time, it is necessary to evaluate them jointly.

A joint evaluation could consider either the directional accuracy of the two variables or a quantitative measure of the loss associated with making policy based on forecasts of real output growth and inflation. Sinclair et al. (forthcoming) provide the procedures for jointly evaluating the directional accuracy of these variables. They showed that while the directional forecasts, by themselves, were found to not always be valuable, the joint forecasts were valuable overall. However, they did not consider the procedures for jointly evaluating the *quantitative* predictions, nor did they show the impact of the forecast errors on policy.

This paper focuses on this problem by constructing a quantitative policy forecast error measure that is based on a particular policy decision rule. While the methodology for evaluating policy forecast errors is general, for illustration we apply it to the Federal Reserve's decision rule for setting monetary policy. The next section presents the policy forecast error measure. Subsequent sections present the data, the Fed's implicit policy rule, the evaluation procedure, the results, robustness checks, and our conclusions.

I. Methodology for Combining the Forecast Errors

In order to jointly evaluate forecasts of any two or more variables simultaneously, an appropriate weighted measure is needed to combine the errors of the variables. We suggest that forecasts of multiple series are generally generated for a specific policy purpose, whether the forecasts are used as inputs for monetary policy, fiscal policy, a firm's pricing policy, or for any other use.

Specifically, let $P_{t,t+h}^f$ be a policy decision at time t that is a linear function of the h -step ahead forecasts of $N \geq 1$ variables ($x_{i,t+h}^f, i = 1, \dots, N$). The superscript f indicates that the policy decision is based on forecasts rather than the actual outcomes of the variables:

$$P_{t,t+h}^f = p(x_{1,t+h}^f, \dots, x_{N,t+h}^f). \quad (1)$$

If policymakers have perfect foresight, the policy decision would simply be P_t without the superscript f :

$$P_{t,t+h} = p(x_{1,t+h}, \dots, x_{N,t+h}). \quad (2)$$

However, because policy is based on forecasts, rather than on the actual data, policy is subject to errors which are functions of the mistakes made in forecasting the underlying variables $x_{i,t}, i = 1, \dots, N$. We call the difference between the actual policy and the policy that would have been pursued under perfect foresight the policy forecast error (PFE):

$$PFE_t = P_{t,t+h} - P_{t,t+h}^f = p(x_{1,t+h}, \dots, x_{N,t+h}) - p(x_{1,t+h}^f, \dots, x_{N,t+h}^f) = e(e_{1,t+h}, \dots, e_{N,t+h}), \quad (3)$$

where $e_{1,t+h}, \dots, e_{N,t+h}$, are the forecast errors associated with the individual series. Thus the PFE is composed of the individual forecast errors weighted by their importance in the policy rule.

As noted in the introduction, the standard practice has been to separately evaluate the forecast errors of each of the individual series which enter the policy decision function. It is

common to compute some measure of forecast accuracy (such as root mean squared forecast error-RMSFE, for example) to use in a comparison with other forecasts. These standards of comparison could be either a naïve benchmark or forecasts generated by another set of forecasters. But, in a policy decision environment, such comparisons are difficult to interpret for at least three reasons. First, it is often difficult to make general statements about relative forecast ability because one forecaster may have a lower RMSFE for a subset of the forecasted variables and a higher RMSFE for the other forecasted variables. Second, single variable comparisons ignore the ultimate objective of the forecasts which serve as inputs to the policy decision. By examining the errors of each variable separately, we are implicitly assigning equal weights (in the policy decision function) to all variables being forecasted. Finally, single variable comparisons ignore the possibility that errors in two or more of the series being considered may, partly or completely, offset each other within the policy decision function. It is for these reasons that we undertake this multivariable evaluation.

II. Data

The data are the Federal Reserve's Greenbook forecasts for each quarter from 1965.4 through 2001.4.¹ The projections used in this analysis are the growth rate of real output (GNP from 1965 to 1991 and GDP from 1992 on)² and the inflation rate (based on the implicit price deflator through the first quarter of 1996, then the chain-weighted price index from 1996.2 on). We only analyze the projections that are made for the current quarter and one quarter ahead.

We focus on short horizons for the following reason. The Fed has, at times, based its Greenbook forecasts on an assumed (possibly varying) path for monetary policy. At other times,

¹ The Greenbook data are only available with a 5-year lag. We obtained our dataset from the PDF files on the Federal Reserve Bank of Philadelphia Website: <http://www.philadelphiafed.org/econ/forecast/greenbook-data/index.cfm>.

² The last forecast in the fourth quarter of 1991 was the first forecast of GDP.

however, the Fed has assumed that monetary policy would remain unchanged over its forecast horizon (see Reifschneider and Tulip, 2007, for further discussion). Since the assumed path for monetary policy associated with each Greenbook forecast is not known, a possible complication arises when analyzing longer-term forecasts. The current quarter and one-quarter ahead forecasts are too short of a time horizon, however, to be affected by the Fed's future path for monetary policy. Therefore, regardless of whether the Fed assumes a constant path or a varying path for monetary policy, the current and one-quarter-ahead forecasts will be unaffected by those assumptions.

In the Greenbook there are at least two forecasts per quarter, each made in various months of the quarter. Consequently the forecasts made for the current and next quarter have leads of zero to five months to the end of the relevant quarter. These leads are the horizons of the forecasts. Thus, horizons 0 through 2 are forecasts for the current quarter; with horizon 0 being the forecast made in the last month of the quarter but before all the data that refer to that quarter have been released. Similarly, horizons 3 through 5 are forecasts made for one quarter ahead (so the horizon 0 and horizon 3 forecasts were made at the same time). Because forecasts were not made at all horizons in every quarter, the number of observations differs between horizons.

The actual figures were the data published approximately 90 days after the end of the quarter to which they refer.³ Use of the real time data avoids definitional and classification changes.

³ These are thus, in modern terminology, the "final" releases by the Bureau of Economic Analysis. Our results are robust to using instead the data published 45-60 days after the end of the quarter.

III. The Fed's Policy Rule

In order to show the effects of the Federal Reserve's forecasts of real output growth and the inflation rate, it is necessary to first establish an appropriate policy rule. We assume that the Fed implicitly follows the Taylor rule (Taylor, 1993) as the monetary policy rule. Although Taylor (1993) originally proposed his rule as an empirical description of past Fed policy actions, Woodford (2001a, 2001b) has shown that the Taylor rule can also be justified based on a firm theoretical foundation. The Taylor rule can be derived from an optimizing macro model in which the monetary authority attempts to minimize a quadratic loss function of the form:

$L_t = \pi_t^2 + \lambda(y_t - y_t^e)^2$, where π is inflation, y is output, λ is a positive constant and y_t^e is the efficient level of output (Woodford, 2001a). Woodford (2001b) showed that this loss function approximates the loss function in a representative household's optimization problem. Moreover, under the assumptions that the dynamic behavior of the economy is linear and the objective function of the Fed is quadratic, the optimal policy is certainty equivalent (Mishkin, 2008). The application of certainty equivalence requires interest rate smoothing (Giannoni and Woodford, 2002); however including lagged interest rate terms does not affect our policy forecast errors because the smoothed interest rate terms in each rule would cancel each other out.

If the Fed were to follow this policy rule in real time, it would require "now-casts," i.e. forecasts for the current quarter, for both inflation and output, due to the lag in data availability. Further research has also suggested that the Taylor rule should be forward-looking, employing expected future values of both output and inflation (see Clarida et al, 2000).

According to the forward-looking Taylor rule, the Fed, sets a target federal funds rate, i_t^{Tf} , based on equation (4), where, as above, the superscript “f” denotes that the target is based on forecasted variables.⁴ The Fed’s policy decision ($P_{t,t+h}^f$) is written as:

$$P_{t,t+h}^f = i_t^{Tf} = r^* + \pi_{t+h}^f + 0.5(\pi_{t+h}^f - \pi^*) + 0.5(y_{t+h}^f - y^*), \quad (4)$$

where r^* is the equilibrium real interest rate, π^* is the Fed’s implicit inflation rate target, and y^* is the potential output growth rate.⁵ The Fed forecasts both inflation, π_{t+h}^f , and output growth, y_{t+h}^f , h periods ahead. The robustness of our choice of the original Taylor (1993) weights of 0.5 on both the inflation and output gaps will be explored in Section VI.

The actual outcome in period $t+h$, however, may differ from the Fed’s forecasts.

Therefore, if the members of the FOMC had known the actual values for π_{t+h} and y_{t+h} (i.e. if they had perfect forecasts or perfect foresight), they would have chosen a (potentially different) federal funds rate. Consequently, their policy decision under perfect foresight ($P_{t,t+h}$) would have been:

$$P_{t,t+h} = i_t^T = r^* + \pi_{t+h}^A + 0.5(\pi_{t+h}^A - \pi^*) + 0.5(y_{t+h}^A - y^*), \quad (5)$$

where π_{t+h}^A and y_{t+h}^A represent the actual realizations of π_{t+h} and y_{t+h} . The difference between i_t^{Tf} and i_t^T measures the difference in the Fed funds rate that occurs because of inaccurate forecasts

⁴ Following Orphanides (2001), we assume that the Fed uses the Greenbook forecasts in their decision rule. The members of the FOMC also make their own forecasts, but have access to the staff forecasts of the Greenbook when doing so. For an evaluation of those forecasts, see Romer and Romer (2008).

⁵ While the output gap is typically used in the Taylor rule, the growth rate is typically used in forecast evaluation. The growth rate of the actuals is approximately $\ln(Y_t) - \ln(Y_{t-1})$, whereas the growth rate of the forecasts is approximately $\ln(Y_t^f) - \ln(Y_{t-1}^f)$. Thus, when we subtract one from the other for the policy forecast error, we have $\ln(Y_t) - \ln(Y_t^f)$. Approximating the output gaps in the same manner, we have $\ln(Y_t) - \ln(Y^*)$ and $\ln(Y_t^f) - \ln(Y^*)$, so again we have $\ln(Y_t) - \ln(Y_t^f)$. It is this result that permits us to use the growth rate in order to construct the PFEs. This analysis does assume, however, that potential output, Y^* , is known rather than a forecast. This assumption is based on the lack of forecasts for this variable in the Greenbook. For a discussion of the role of real time output gap estimates and the Taylor rule, see Orphanides (2001).

of output growth and inflation and thus represents the Federal Reserve's policy forecast error,

PFE_t :

$$PFE_t = i_t^T - i_t^{Tf} = 1.5(\pi_{t+h}^A - \pi_{t+h}^f) + 0.5(y_{t+h}^A - y_{t+h}^f). \quad (6)$$

The differences, $(\pi_{t+h}^A - \pi_{t+h}^f)$ and $(y_{t+h}^A - y_{t+h}^f)$, are the Fed's forecast errors for the inflation rate and real output growth respectively. Given the PFEs, the evaluation procedures are similar to those used in judging individual forecast errors.

Working with the PFE of the Fed allows us to focus on the impact of forecast errors on the policy rule without explicitly estimating the policy rule.⁶ This means that we do not use the interest rate, the equilibrium real interest rate, the Fed's implicit inflation rate target, or potential output in our analysis. Considerable research has gone into estimating these variables (e.g. Clark and Kozicki, 2005, for the equilibrium real interest rate and Leigh, 2008, for the Fed's implicit inflation rate target). While these variables may be time varying, as long as they are known to the policymaker each quarter, they drop out of our expression.

IV. Evaluation Procedure

We calculate the mean absolute policy forecast errors (MAPFE) and root mean squared policy forecast errors (RMSPFE) for the full sample as well as for the sub-sample where we have alternative forecasts available for comparison. We test for bias and compare these errors with forecasts obtained from two standards of comparison: a naïve model and the Survey of Professional Forecasters (SPF).

A. Testing for Bias

Holden and Peel (1990) showed that a necessary condition for bias is that the mean error be significantly different from zero. We test for bias in the traditional way by regressing the PFE

⁶ For a discussion of the impact of using projections on the estimates of the Taylor rule, see Orphanides and Wieland (2008).

on a constant and use a t-test that the constant is zero. This statistic will be calculated separately for each forecast horizon for the entire period as well as for alternative subsamples detailed below.

B. Standards of Comparison

In order to evaluate the policy losses attributable to the forecasts, we develop two standards of comparison: the PFEs that would have occurred if (1) naïve forecasts had been used to set the policy or (2) if the median forecasts from the Survey of Professional Forecasters had been used. In each case, the comparison uses the same weights and has the same number of observations as were used in constructing the loss functions associated with the Fed forecasts that we are evaluating.

The naïve (same-change) forecast assumes that the same growth rate of output and the same growth rate in the price level (the inflation rate) as were observed in the previous quarter will occur in the future period(s). These forecasts are the real-time data, published in the Greenbook, on GDP growth and inflation rate for the quarter before the Greenbook forecasts were made. This assures that we have the information available to the forecasters at the time the predictions were made.

We also compare the Greenbook forecasts to the median forecasts from the Survey of Professional Forecasters (SPF). These data come from the Federal Reserve Bank of Philadelphia (for a description of this survey, see Croushore, 1993). The individuals who respond to the SPF report their forecasts of real and nominal output (plus other variables not considered here). We use the median forecasts from this survey to construct forecasts comparable to our Greenbook data. Since the SPF forecasts are only reported once per quarter (in the middle of the second

month of each quarter), we only have data comparable to horizons one and four. The comparable SPF forecasts are available beginning with the third quarter of 1981.

We use Theil's U-statistic to compare the root mean squared policy forecast errors made by the Fed in the Greenbook with those obtained from the two standards of comparison. It should be noted that if there were only one forecast used in the policy rule this statistic would be the U statistic normally used in forecast evaluation. Thus, our methodology, when applied to a single variable, is the same as the traditional single variable forecast evaluation procedure. The statistic is:

$$U = \frac{RMSPFE_{Fed}}{RMSPFE_{alternative}}, \quad (7)$$

where the alternative is either the naïve forecast or the median forecast from the SPF.

In addition to reporting the U-statistic, we also utilize the Diebold-Mariano (1995) test to determine whether the Fed's policy forecast errors are significantly different from those generated by each of the two alternative forecasts. We employ the modification recommended by Harvey et al. (1997) which results in an improvement in the behavior of the test statistic for moderately-sized samples:

$$S_1^* = S_1 \left(\frac{T+1-2(h+1)+h(h+1)/T}{T} \right)^{-\frac{1}{2}}, \quad S_1 = \frac{\bar{d}}{[\hat{V}(\bar{d})]^{1/2}} \quad (8)$$

where h is the horizon, \bar{d} is the mean absolute difference of the prediction errors, $\hat{V}(\bar{d})$ is the estimated variance, S_1 is the original DM statistic, and S_1^* is the modified DM statistic. The modified Diebold-Mariano (DM) test statistic is estimated with Newey-West (1987) corrected standard errors that allow for heteroskedastic autocorrelated errors.

V. Results

Figures 1 and 2 show the policy forecast errors for the zero month horizon and the three month horizon respectively (other horizons are similar). The y-axis is expressed in percentage points and can be interpreted as the amount by which the federal funds rate would have differed by using forecasts in the policy rule instead of the realized data. A positive policy forecast error suggests that the federal funds rate would have been set higher had the actual data rather than the forecasts been used. The mean absolute policy forecast error (MAPFE) based on Fed forecasts at the zero month horizon is 101 basis points for the entire sample 1965:4-2001:4 (Table 1). In general, Fed policy based on the Taylor rule was at least a full percentage point away from the intended target because of errors in forecasting growth and inflation at the zero horizon.

Table 1 also shows the root mean squared policy forecast errors (RMSPFE) for the samples and horizons we analyze in our subsequent tests. As expected, both the MAPFE and RMSPFE increase with the length of the forecast horizon and both are smaller than those of the naïve forecasts. This result is consistent with previous findings from evaluations of a single variable. Similar results hold for the sub-period that is used for a comparison with the SPF data. The results for this sub-period do suggest a small amount of improvement in terms of smaller MAPFE and RMSPFE in the more recent period. The similarity of these results with the full sample results, however, suggests that our findings for the full-sample are not dependent upon the possibility that the Fed did not follow the Taylor Rule in the earlier part of the sample.⁷ Furthermore, the improvement is also present for the naïve forecasts.

Table 2 presents the results from our tests for bias. It shows that the null of no bias (zero mean) in the PFE is not rejected at the 5% for the entire period, 1965.4-2001.4, or for the subsample corresponding to the availability of the SPF forecasts, 1981.3-2001.4.

⁷ This subsample is representative of several alternative subsamples we explored.

In addition to testing for bias we compared the policy forecast error based on Fed forecasts with the policy forecast errors based on our two alternative sets of forecasts: the naïve forecast and the median SPF forecast. Our two measures of comparison are Theil's U-statistic (Tables 3 and 4) and the modified Diebold-Mariano test (Tables 5 and 6).

The U-statistics reported in Tables 3 and 4 show that overall, the PFEs are smaller than those that would have been obtained if the forecasts from a naïve model had been used to set policy. The U statistics are all less than 1 (see Table 3), with little difference between the full sample and the sample starting in 1981.3. Similarly, the actual Fed policy forecast errors are smaller than they would have been if the median SPF forecast had been used for policy purposes (see Table 4).

Although the PFEs associated with the Fed's forecasts are smaller than those of alternative forecasts, the question is whether or not they are significantly smaller. To determine significance, we employ the modified Diebold Mariano test of equal predictive ability. Table 5 shows the results of the comparison of the Fed's policy forecast errors and the policy forecast errors that would result from using the naïve forecast in the policy decision rule. We find that the gap between the absolute value of the naïve policy forecast error and the Fed's policy forecast error is statistically significant at the 5% level for all horizons for both sub-samples (except for horizon 2 in the 1981.3-2001.4 subsample which is significant at the 10% level). The results in Table 6 show, however, that the Fed's policy forecast errors are not significantly smaller than the policy forecast errors generated by the SPF at either horizon for which the SPF forecasts are available.⁸

⁸ Similar results were found for inflation alone by Gamber and Smith (2008).

VI. Robustness to the Policy Rule Weights

In our analysis we have chosen to focus on the policy rule as initially formulated in Taylor (1993). Since then there has been, however, a long literature estimating the policy rule actually used by the Fed (e.g. Clarida et al, 2000; Orphanides, 2001). One focus of this literature, and the part relevant to our analysis, is the weights used on inflation and output. To address the possibility that the Fed uses weights other than the Taylor weights, we performed a simple exercise. While the Fed may choose their weights based on many criteria, we focus on the weights which show the minimum impact of the forecast errors on the policy instrument. We thus determined the weights that minimize the RMSPFE of the Fed's forecasts (similar results were found when we instead minimized the MAPFE). While we calculated different weights for each horizon, the weights were constant for the full sample. These weights are listed in the first two columns of Table 7. These weights are surprisingly similar to the Taylor weights.

Then, following Clarida et al (2000), we divided the sample into two periods and allowed for weights that might differ over the two periods. The first period was for the pre-Volker Fed, from 1965.4 through 1979.2, and the other period was for the Volker-Greenspan Fed from 1979.3-2001.4. These weights are in the last columns of Table 7.⁹ These weights do not necessarily imply anything about actual Fed behavior, but they allow us to find the minimum MAPFE and RMSPFE for the policy if those weights had been used. Any other weights used by the Fed would increase the impact of forecast errors on the policy instrument, so these results give us a lower bound. The minimum RMSPFE and MAPFE are presented in Tables 8 and 9. These results are very similar to what we found using the Taylor weights. Based on these tables

⁹ We also estimated the PFEs using the weights found by Clarida et al (2000) in their analysis and found that our results were robust to that choice of weights as well.

our conclusion still holds that the impact of forecast errors alone on the monetary policy rule is approximately 100 basis points.

VII. Conclusions

In this paper we developed a methodology in order to evaluate the impact of forecast errors on the Fed's monetary policy as characterized by the Taylor rule. We find that the Fed's policy forecast error is unbiased and significantly smaller than the errors that would have resulted from naïve forecasts but not from the SPF predictions. Nevertheless, the mean absolute policy forecast error of the Fed forecasts is approximately 100 basis points.

Moreover, we want to emphasize this methodology can be applied in the context of any policy decision rule. This methodology will be useful for the policy decisions in both the public and private sectors. Some policy applications include evaluating future budget plans for government programs, health policies, and environmental policies. For private decision makers, we could evaluate inventory decisions which depend on forecasted sales, costs, and real interest rates, using a decision rule such as the one discussed in Maccini et al. (2004).

(NBER Recessions in Gray)

**Table 1: Mean Absolute Policy Forecast Error (MAPFE) and
Root Mean Squared Policy Forecast Error (RMSPFE)**

Panel A: Full Sample Fed and Naïve Forecasts

Sample	horizon	MAPFE_{Fed}	MAPFE_{naïve}	RMSPFE_{Fed}	RMSPFE_{naïve}	N
1965.4-2001.4	0	1.01	1.94	1.32	2.76	156
1965.4-2001.4	1	1.26	2.10	1.68	2.84	109
1966.1-2001.4	2	1.55	1.99	1.95	2.69	90
1966.1-2001.4	3	1.57	2.32	2.08	3.05	156
1965.4-2001.4	4	1.83	2.42	2.35	3.16	104
1967.2-2001.4	5	1.86	2.43	2.48	3.19	84

Panel B: 1981.3 – 2001.4 (Corresponds to the SPF Sample Period)

Sample	horizon	MAPFE_{Fed}	MAPFE_{naïve}	RMSPFE_{Fed}	RMSPFE_{naïve}	N
1981.3-2001.4	0	0.92	1.72	1.17	2.35	80
1981.3-2001.4	1	0.96	1.79	1.34	2.26	49
1982.1-2001.4	2	1.26	1.72	1.49	2.29	35
1981.4-2001.4	3	1.16	1.92	1.54	2.46	80
1981.4-2001.4	4	1.49	2.16	1.89	2.69	49
1982.2-2001.4	5	1.13	1.76	1.54	2.11	35

Panel C: SPF Sample Period Fed and SPF Forecasts

Sample	horizon	MAPFE_{Fed}	MAPFE_{SPF}	RMSPFE_{Fed}	RMSPFE_{SPF}	N
1981.3-2001.4	1	0.96	1.11	1.34	1.41	49
1981.4-2001.4	4	1.49	1.72	1.89	2.44	49

Table 2: Tests for Unbiasedness of Fed’s Policy Forecast Errors, Alternative Sample Periods

Panel A: 1965.4 – 2001.4 (Full Sample)

Horizon (months)	0	1	2	3	4	5
Estimated mean	0.06	0.16	0.11	0.21	0.32	0.51
Std. Error	0.11	0.16	0.21	0.17	0.23	0.27
P-value (H_0 : zero mean)	0.58	0.33	0.59	0.21	0.17	0.06
Number of Observations	156	109	90	156	104	84

Panel B: 1981.3 – 2001.4 (Corresponds to the SPF Sample Period)

Horizon (months)	0	1	2	3	4	5
Estimated mean	-0.16	0.03	-0.22	-0.22	-0.41	-0.28
Std. Error	0.13	0.19	0.25	0.17	0.27	0.26
P-value (H_0 : zero mean)	0.23	0.89	0.39	0.21	0.13	0.28
Number of Observations	80	49	35	80	49	35

Table 3: U Statistics for Fed PFEs Compared to PFEs Based on Same-Change Naïve Model

Panel A: Current Quarter

Horizon (months)	0	1	2
U Statistic, Full Sample, 1965.4 – 2001.4	0.48	0.59	0.73
U Statistic, SPF Sample, 1981.3 – 2001.4	0.50	0.59	0.65

Panel B: 1 Quarter Ahead

Horizon (months)	3	4	5
U Statistic, Full Sample, 1965.4 – 2001.4	0.68	0.75	0.78
U Statistic, SPF Sample, 1981.4 – 2001.4	0.63	0.70	0.73

Table 4: U Statistics for Fed PFEs Compared to PFEs Based on the SPF

Horizon (months)	1	4
U Statistic, SPF Sample, forecasts made 1981.3 – 2001.4	0.95	0.84

Table 5: Modified Diebold Mariano Test of Equal Predictive Ability: Fed versus Naïve

Panel A: Full Sample

Sample	Horizon	Average Gap Naïve PFE - Fed PFE	Modified DM stat. H ₀ : Gap=0	N
1965.4-2001.4	0	0.93**	5.94	156
1965.4-2001.4	1	0.84**	5.04	109
1966.1-2001.4	2	0.43*	2.33	90
1966.1-2001.4	3	0.76**	4.33	156
1965.4-2001.4	4	0.58**	3.02	104
1967.2-2001.4	5	0.57*	2.47	84

Note: ** denotes significance at 1%, * denotes significance at 5%, † denotes significance at 10%.

Panel B: 1981.3 – 2001.4 (Corresponds to the SPF Sample Period)

Sample	Horizon	Average Gap Naïve PFE - Fed PFE	Modified DM stat. H ₀ : Gap=0	N
1981.3-2001.4	0	0.81**	4.75	80
1981.3-2001.4	1	0.83**	5.08	49
1982.1-2001.4	2	0.46†	1.98	35
1981.4-2001.4	3	0.76**	5.1	80
1981.4-2001.4	4	0.67**	4.22	49
1982.2-2001.4	5	0.63**	4.32	35

Note: ** denotes significance at 1%, * denotes significance at 5%, † denotes significance at 10%.

Table 6: Modified Diebold Mariano Test of Equal Predictive Ability: Fed versus SPF

Sample	horizon	Average Gap SPF PFE - Fed PFE	Modified DM stat. H ₀ : Gap=0	N
1981.3-2001.4	1	0.15	1.48	49
1981.4-2001.4	4	0.22	1.59	49

Note: ** denotes significance at 1%, * denotes significance at 5%, † denotes significance at 10%

Table 7: Weights that Minimize RMSPFE for the Fed Forecasts

Horizon	Full Sample Weights		Split-Sample Weights			
	GDP Weight	Inflation Weight	GDP Weight		Inflation Weight	
			1965.4 – 1979.2	1979.3 – 2001.4	1965.4 – 1979.2	1979.3 – 2001.4
0	0.70	1.30	0.77	0.57	1.23	1.43
1	0.57	1.43	0.69	0.37	1.31	1.63
2	0.56	1.44	0.65	0.35	1.35	1.65
3	0.52	1.48	0.67	0.32	1.33	1.68
4	0.49	1.51	0.64	0.22	1.36	1.78
5	0.64	1.36	0.73	0.40	1.27	1.60

Table 8: RMSPFE for Different Weights

Sample	horizon	Taylor RMSPFE _{Fed}	Full Sample Min Weights RMSPFE _{Fed}	Split Sample Min Weights RMSPFE _{Fed}
1965.4-2001.4	0	1.32	1.25	1.23
1965.4-2001.4	1	1.68	1.67	1.61
1966.1-2001.4	2	1.95	1.94	1.88
1966.1-2001.4	3	2.08	2.08	1.99
1965.4-2001.4	4	2.35	2.35	2.19
1967.2-2001.4	5	2.48	2.40	2.30

Table 9: MAPFE for Different Weights

Sample	horizon	Taylor MAPFE _{Fed}	Full Sample Min Weights MAPFE _{Fed}	Split Sample Min Weights MAPFE _{Fed}
1965.4-2001.4	0	1.01	0.96	0.96
1965.4-2001.4	1	1.26	1.24	1.20
1966.1-2001.4	2	1.55	1.56	1.49
1966.1-2001.4	3	1.57	1.57	1.52
1965.4-2001.4	4	1.83	1.83	1.68
1967.2-2001.4	5	1.86	1.85	1.72
